MIGRATION OF BODIES FROM THE ZONE OF THE OUTER ASTEROID BELT TO THE EARTH. S. I. Ipatov, V.I. Vernadsky Institute of Geochemistry and Analytical Chemistry of RAS, Moscow, Russia (siipatov@hotmail.com)

Introduction: Migration of bodies to the Earth from different distances from the Sun was considered in several papers. Such papers were discussed in [1]. Earlier we studied migration of planetesimals to planets mainly from the zones beyond the orbit of Jupiter [14]. Migration of bodies-planetesimals with initial semimajor axes between 3 and 5 AU is considered below.

Initial data: Gravitational influence of 7 planets (from Venus to Neptune) was taken into account with the use of the symplectic code from [5]. In some calculations a step of integration equaled to 10 days, in other calculations it was equal to 15 days. In each variant of the calculations, the initial values of semi-major axes of orbits of 250 bodies-planetesimals varied from $a_{\text {min }}$ to $a_{\text {min }}+0.1 \mathrm{AU}$, their initial eccentricities equaled to $e_{0}$, and the initial inclinations equaled to $e_{0} / 2 \mathrm{rad}$. The number of planetesimals with a semi-major axis $a$ was proportional to $a^{1 / 2}$. The values of $a_{\min }$ varied from 3 to 4.9 AU. In Table 1 I present the results of calculations at $e_{0}=0.02$ and in Table 2 at $e_{0}=0.15$. Orbital elements of migrated planetesimals were recorded in computer memory with a step of 500 years. Based on these arrays of orbital elements, I calculated the probabilities $p_{\mathrm{E}}$ of collisions of bodies-planetesimals with the Earth during time interval $T$ (up to 5 Gyr in some variants). The calculations of $p_{\mathrm{E}}$ were made similar to the calculations presented in [1-4, 6-8]. The value of $p_{\mathrm{E}}$ is the ratio of the sum of the probabilities of collisions of 250 bodies with the Earth to 250 . For some bodies such probabilities can be equal to 0 . In the tables the values of $p_{\mathrm{E}}$ were presented for $10,100 \mathrm{Myr}$, and for the values of $T$ presented in the tables. The tables also include the number $N_{\text {ell }}$ of bodies-planetesimals left in elliptical orbits.

Results of calculations: The value of $p_{\mathrm{E}}$ could vary by more than a hundred of times for different calculation variants with 250 bodies and the same values of $a_{\text {min }}$ and $e_{0}$ (see lines for $a_{\text {min }}$ equaled to 3.5 AU in Table 1 and to 3.8 and 3.9 AU in Table 2). Such difference was earlier found for calculations of migration of Jupiter-crossing objects [6-7]. One among hundreds or thousands of such objects moved in Earth-crossing orbits during millions or even tens of millions of years, and the probability of a collision of such object with the Earth was greater than the total probability for hundreds or even thousands of other objects. In Tables 1-2 at time interval $T=100 \mathrm{Myr}$, nonzero values of $p_{\mathrm{E}}$ vary from values less than $10^{-6}$ to values of the order of $10^{-3}$, but they are often between $10^{-6}$ and $10^{-5}$, as for many
our previous calculations with $a_{\text {min }} \geq 5$ AU considered in [1-4].

At $T=100 \mathrm{Myr}$ the mean values of $p_{\mathrm{E}}$ for 500 bodies exceeded $2 \times 10^{-5}$ for $a_{\text {min }}=3.2,3.3,3.5,3.7,3.8$, and 4.1 AU both at $e_{0}=0.02$ and $e_{0}=0.15$ (at $e_{0}=0.15$ also for $a_{\text {min }}=4.2 \mathrm{AU}$ ). There were runs with $p_{\mathrm{E}}>10^{-3}$ at $T=100$ $\mathrm{Myr}, a_{\text {min }}=3.5 \mathrm{AU}, e_{0}=0.02$, and also at $a_{\text {min }}$ equal to 3.2 and 3.8 for $T=100 \mathrm{Myr}$ and $e_{0}=0.15$. In some runs there was a considerable growth of $p_{\mathrm{E}}$ after 10 and 100 Myr. The growth of $p_{\mathrm{E}}$ by more than $10^{-3}$ at $T>100 \mathrm{Myr}$ were at $a_{\min }=3.0$ and 3.2 AU for $e_{0}=0.15$. These results show that the zone of the outer asteroid belt, especially from 3 to 4 AU , could made a valuable contribution to the delivery of water to the Earth.

After 100 Myr only not more than about $2 \%$ of initial bodies left in elliptical orbits at $a_{\text {min }} \geq 3.8 \mathrm{AU}$ (exclusive for $a_{\min }=4.2 \mathrm{AU}$ ) and $e_{0}=0.02$, and also at $a_{\text {min }} \geq 3.5 \mathrm{AU}$ and $e_{0}=0.15$. For smaller values of $a_{\text {min }}$ some bodies can still move in elliptical orbits even after 5 Gyr.

The fraction $p_{\text {sun }}$ of bodies collided with the Sun during 100 Myr for $e_{0}=0.02$ was less than $4 \%$, and it was less than $2 \%$ at $a_{\min } \leq 3.1 \mathrm{AU}$ and $a_{\min } \geq 3.4 \mathrm{AU}$. For $e_{0}=0.15$ it was less than $9 \%$, and it was less than $1 \%$ at $a_{\text {min }} \leq 3.1 \mathrm{AU}$ and $a_{\text {min }} \geq 3.4 \mathrm{AU}$ (exclusive for $a_{\text {min }}=4.5$ AU with $p_{\text {sun }}$ equal to $1.6 \%$ ). At $T>100 \mathrm{Myr}$ for the considered variants of calculations such inequalities were also true, exclusive for $a_{\text {min }}=3.4 \mathrm{AU}, e_{0}=0.15$, and $T=4 \mathrm{Gyr}$, when the fraction of bodies collided with the Sun reached 17\%.

Conclusions: The probabilities of collisions with the Earth of bodies-planetesimals with initial semimajor axes from 3.2 to 3.4 and from 3.5 to 3.6 AU were usually greater than those for the planetesimals initially located beyond the orbit of Jupiter. The zone of the outer asteroid belt, especially from 3 to 4 AU, could made a valuable contribution to the delivery of water to the Earth.
